Dynorphin/Kappa Opioid Receptor Activity Within the Extended Amygdala Contributes to Stress-Enhanced Alcohol Drinking in Mice

Harold L. Haun, Christina L. Lebonville, Matthew G. Solomon, William C. Griffin, Marcelo F. Lopez, and Howard C. Becker

ABSTRACT

BACKGROUND: While there is high comorbidity of stress-related disorders and alcohol use disorder, few effective treatments are available and elucidating underlying neurobiological mechanisms has been hampered by a general lack of reliable animal models. Here, we use a novel mouse model demonstrating robust and reproducible stress-enhanced alcohol drinking to examine the role of dynorphin/kappa opioid receptor (DYN/KOR) activity within the extended amygdala in mediating this stress-alcohol interaction.

METHODS: Mice received repeated weekly cycles of chronic intermittent ethanol exposure alternating with weekly drinking sessions ± forced swim stress exposure. Pdyn messenger RNA expression was measured in the central amygdala (CeA), and DYN-expressing CeA neurons were then targeted for chemogenetic inhibition. Finally, a KOR antagonist was microinjected into the CeA or bed nucleus of the stria terminalis to examine the role of KOR signaling in promoting stress-enhanced drinking.

RESULTS: Stress (forced swim stress) selectively increased alcohol drinking in mice with a history of chronic intermittent ethanol exposure, and this was accompanied by elevated Pdyn messenger RNA levels in the CeA. Targeted chemogenetic silencing of DYN-expressing CeA neurons blocked stress-enhanced drinking, and KOR antagonism in the CeA or bed nucleus of the stria terminalis significantly reduced stress-induced elevated alcohol consumption without altering moderate intake in control mice.

CONCLUSIONS: Using a novel and robust model of stress-enhanced alcohol drinking, a significant role for DYN/KOR activity within extended amygdala circuitry in mediating this effect was demonstrated, thereby providing further evidence that the DYN/KOR system may be a valuable target in the development of more effective treatments for individuals presenting with comorbidity of stress-related disorders and alcohol use disorder.

https://doi.org/10.1016/j.biopsych.2022.01.002

Stress is commonly regarded as a potent trigger for relapse and a significant factor in promoting excessive alcohol (ethanol) drinking (1–3). There is a high comorbidity between stress-related disorders, including depression, anxiety disorders, and posttraumatic stress disorder, and alcohol use disorder (AUD) (4–8). The prevalence and magnitude of the problem underscores the importance of understanding mechanisms underlying the influence of stress on alcohol use, which is essential for developing new and more effective treatment strategies for individuals with coexisting stress and AUD.

Stress and alcohol exposure influence overlapping systems and neural circuits in the brain, producing adaptations that compromise the ability of individuals to engage in behavioral flexibility that would enhance control over alcohol consumption as well as appropriately respond to stressful events that may provoke return to excessive drinking (9,10). Despite significant advances in our understanding about how stress and alcohol alter brain function, the mechanisms and neurocircuits underlying the complex interactions between stress and alcohol consumption are not fully understood (11). Indeed, demonstrating reliable and consistent effects related to the interaction between stress and alcohol drinking in animal models has been challenging (12–14). The general lack of reliable preclinical models has, at least in part, impeded progress toward developing effective therapeutics that especially target stress-related excessive drinking.

To address this shortcoming, we developed a mouse model wherein repeated brief forced swim stress (FSS) exposure interacts with chronic intermittent ethanol (CIE) exposure to enhance alcohol drinking in dependent (CIE-exposed) mice but not alter more moderate stable intake in nondependent mice (15,16). Corroborating an earlier study in rats (17), this stress-enhanced drinking in CIE-exposed mice is robust and reproducible, having been demonstrated by other research groups as well (18–20). Increased drinking in mice with a history of both chronic alcohol exposure and stress experience provides an ideal opportunity to use this...
CIE-FSS drinking model to probe mechanisms and potential targets relevant to the problem of stress-related excessive alcohol drinking.

Because both stress and chronic alcohol engage the dynorphin/kappa opioid receptor (DYN/KOR) system, the role of this neuropeptide system in chronic alcohol-related dysphoria and elevated drinking has gained increasing attention (21–23). DYNs are peptides derived from the precursor Pdyn (prodynorphin) that preferentially bind to KORs, producing physiological and behavioral effects via inhibitory G-protein coupling and other signaling cascades (24–27). KOR activation has been shown to produce aversive/dysphoric effects as indicated by measures of conditioned avoidance and anxiety-like and depression-like behavior (28,29). Stress exposure activates the DYN/KOR system, eliciting dysphoria and anxiety-like behaviors (30) along with elevated DYN immunoreactivity in brain regions that are integral to reward and stress circuitry involved in alcohol/drug addiction (31).

Pharmacological manipulation of DYN/KOR activity has been shown to alter behavioral responses to stress and motivational effects of alcohol in a variety of experimental conditions (22,32). Systemic administration of KOR antagonists has been shown to reduce high levels of alcohol consumption associated with dependence and binge-drinking models in rats (33,34) and mice (20,35,36). Evidence points to involvement of the extended amygdala in mediating these effects. Interconnected brain structures comprising extended amygdala circuitry, including the nucleus accumbens, central amygdala (CeA), and bed nucleus of the stria terminalis (BNST), are rich in DYN and KOR and highly responsive to alcohol exposure (37–41). Direct infusion of the KOR antagonist norbinaltorphimine (norBNI) into these structures reduces excessive alcohol drinking in models of dependence (42–44) and binge-like drinking (35,45). While we recently demonstrated that systemic administration of a KOR antagonist can block the ability of stress to enhance alcohol consumption (36), the site of action mediating this effect is not known.

This series of studies was designed to probe the role of DYN/KOR activity in two prominent structures within extended amygdala circuitry (CeA and BNST) as it relates to stress-enhanced alcohol drinking. Specifically, our CIE-FSS drinking model was used to 1) examine how a history of CIE and FSS exposure, alone and in combination, affects expression of Pdyn messenger RNA (mRNA) within the CeA; 2) determine the effect of targeted chemogenetic silencing of DYN-expressing neurons within the CeA (CeA_{DYN} neurons) on stress-enhanced alcohol drinking; and 3) determine the contribution of KOR signaling within the CeA and BNST in mediating the ability of stress to further enhance elevated alcohol consumption associated with dependence. Results from these studies provide critical evidence indicating that a history of chronic alcohol exposure and stress engage the DYN/KOR system within the extended amygdala in mediating stress-enhanced drinking. As such, these findings support recent clinical efforts devoted to evaluating the therapeutic value of targeting this neuropeptide system in reducing heavy drinking in individuals comorbid with stress-related disorders and AUD (46).

METHODS AND MATERIALS
A detailed description of all experimental procedures, including the CIE-FSS drinking model, assays for Pdyn mRNA measurement, stereotaxic surgery, virus and drug infusions, histology, and drug preparations, is provided in the Supplement.

CIE and FSS Drinking Model
All studies involved use of adult male C57BL/6J mice and Pdyn-IRES-Cre mice (35,47) treated in the CIE-FSS drinking model as previously described (15,16,36). Briefly, after establishing stable 1-hour daily ethanol (15% vol/vol) intake, mice were separated into four groups: control (CTL), CIE-alone, FSS-alone, and CIE+FSS. Mice received CIE vapor or air exposure in inhalation chambers followed by test drinking sessions for 5 consecutive days. This pattern of weekly CIE (or air) exposure alternating with weekly test drinking sessions was repeated for three or four cycles (Figure 1). Mice in the FSS-alone and CIE+FSS groups experienced brief (10 min) FSS exposure 4 hours prior to each of the test drinking sessions. The remaining nonstressed mice (CTL and CIE groups) were left in their home cage undisturbed.

Study Procedures
Effects of CIE and FSS Exposure on Pdyn mRNA Expression in the CeA. C57BL/6J mice treated in the CIE-FSS drinking model were sacrificed on the final day of test 4 at 30 minutes, 4 hours, or 24 hours after FSS exposure (or at equivalent times for no-stress groups) (n = 6–10/group/time point). Collection of CeA samples, RNA extraction, and Taqman quantitative reverse transcription polymerase chain reaction assays were performed as previously described (48,49).

Effect of Chemogenetic Inhibition of DYN-Expressing Neurons in the CeA on Alcohol Drinking in the CIE-FSS Model. Adult male Pdyn-IRES-Cre mice received bilateral infusions of a Cre-dependent virus containing an inhibitory DREADD (designer receptor exclusively activated by designer drugs) (AAV8-hSyn-DIO-HM4Di-mCherry) (n = 10 or 11/group) or control virus (AAV8-hSyn-DIO-mCherry) (n = 6 or 7/group) into the CeA to target CeA_{DYN} neurons as previously described (35). After at least 2 weeks of recovery, the baseline phase of the study commenced. On day 2 and day 4 of test 3, mice were injected intraperitoneally with vehicle (0.9% saline) or clozapine N-oxide (CNO) (3 mg/kg) to activate the DREADD. The order of drug administration was counterbalanced for each group.

Effect of KOR Antagonism in the CeA or BNST on Alcohol Drinking in the CIE-FSS Model. C57BL/6J mice received bilateral guide cannula positioned above the CeA (n = 7–9/group) or BNST (n = 8–10/group) (35,45). After at least 2 weeks of recovery, baseline drinking commenced. At 16 hours prior to the start of the drinking session on day 3 of test 3, separate groups of mice in each experimental condition received microinjection of the KOR antagonist norBNI (2.5 μg/side) or vehicle (1× phosphate-buffered saline) into the CeA or BNST.

Neurons within the CeA (CeA effect of targeted chemogenetic silencing of DYN-expressing

DYN/KOR activity in two prominent structures within extended amygdala circuitry (CeA and BNST) as it relates to stress-enhanced alcohol drinking. Specifically, our CIE-FSS drinking model was used to 1) examine how a history of CIE and FSS exposure, alone and in combination, affects expression of Pdyn messenger RNA (mRNA) within the CeA; 2) determine the effect of targeted chemogenetic silencing of DYN-expressing neurons within the CeA (CeA_{DYN} neurons) on stress-enhanced alcohol drinking; and 3) determine the contribution of KOR signaling within the CeA and BNST in mediating the ability of stress to further enhance elevated alcohol consumption associated with dependence. Results from these studies provide critical evidence indicating that a history of chronic alcohol exposure and stress engage the DYN/KOR system within the extended amygdala in mediating stress-enhanced drinking. As such, these findings support recent clinical efforts devoted to evaluating the therapeutic value of targeting this neuropeptide system in reducing heavy drinking in individuals comorbid with stress-related disorders and AUD (46).
Statistical Analysis

Alcohol intake (g/kg) was analyzed by analysis of variance (ANOVA), with group (CTL, CIE, FSS, CIE+FSS) as a between-subjects factor and test cycle (average weekly intake for baseline and tests 1–4) as a repeated measure. Pdyn mRNA expression in the CeA was expressed as a fold change from the CTL condition and analyzed at each time point by ANOVA, with group as the main factor. For microinjection studies, ANOVAs included group and drug (norBNI vs. vehicle) as between-subject variables and drug (CNO vs. saline) as a repeated measure. For microinjection studies, ANOVAs included group and drug (norBNI vs. vehicle) as between-subject variables and day as a repeated measure in analyses of alcohol consumption (average of days 3 and 4) and difference in intake from baseline and tests 1 to 4 as a repeated measure. In chemogenetic and pharmacological studies, only data from subjects in which targeted viral expression or placement of microinjectors were verified as correct were used in analyses.

RESULTS

Combined CIE and Stress (FSS) Exposure Increases Pdyn mRNA Expression in the CeA

While alcohol consumption remained relatively stable over successive test cycles in the FSS-alone and CTL groups, intake increased above baseline levels in the CIE-exposed groups, with this effect most robust in the CIE+FSS group (Figure 2A, B). This was supported by a significant group × test cycle interaction (F_{12,332} = 5.942, p < .001), which revealed a modest increase in alcohol consumption in the CIE-alone group, with intake during test 2 and test 4 greater than baseline (ps < .05). Alcohol intake in the CIE+FSS group was greater during all test weeks compared with their baseline level of intake (ps < .001), and drinking was greater during each test week in the CIE+FSS condition compared with the CIE-alone group (ps < .05). Separate analysis of alcohol intake during the final test period prior to sacrifice (test 4) revealed a main effect of group (F_{3,86} = 13.025, p < .001). While alcohol intake for CIE-alone and FSS-alone groups did not significantly differ from the CTL group, CIE+FSS mice exhibited greater alcohol intake than all other groups (ps < .001) (Figure 2C). These results confirm our previous findings that FSS experience selectively enhances alcohol drinking in dependent (CIE-exposed) mice while not altering intake in nondependent (FSS-alone) mice (15,16,36).

Analysis of Pdyn mRNA expression in the CeA at the end of test 4 revealed main effects of group at 30 minutes (F_{3,80} = 7.055, p < .001) and 4 hours (F_{3,80} = 3.33, p = .037) following the last FSS exposure but not at 24 hours after FSS (F_{3,80} = 0.415, p = .744). Post hoc analyses showed that Pdyn mRNA expression was selectively elevated in the CIE+FSS group relative to the CTL group at 30 minutes and 4 hours after FSS exposure, with values normalizing at the 24-hour time point (Figure 2D). Neither CIE-alone nor FSS-alone treatments produced an increase in Pdyn mRNA levels in the CeA. Schematic depiction of bilateral tissue punches collected from the CeA is shown in Figure 2E.

Chemogenetic Inhibition of CeA^{Pdyn} Neurons Reduces Stress (FSS)-Enhanced Alcohol Drinking in CIE-Exposed Pdyn-ires-Cre Mice

Pdyn-ires-Cre mice were used to target expression of an inhibitory (hM4Di) DREADD or control virus in CeA^{Pdyn} neurons (Figure 3A). Using this same strategy, we previously demonstrated fidelity of expression and functionality of this viral vector (85). In this study, expression of the mCherry marker was confined to the CeA (Figure 3B). Information on average weekly alcohol intake prior to administering CNO during test 3 is provided in Table 1. ANOVA
revealed a main effect of group ($F_{3,60} = 8.397, p < .001$) and test cycle ($F_{2,120} = 22.632, p < .001$) but no effect of virus ($F_{1,60} = 1.895, p = .174$), indicating that viral expression did not influence alcohol drinking prior to testing. A group $×$ test cycle interaction ($F_{3,120} = 6.258, p < .001$) was observed, and post hoc analyses revealed increased alcohol intake in the CIE-alone and CIE+FSS groups during test 1 and test 2 compared with their respective baseline levels of intake ($p < .05$).

Analysis of alcohol intake during test 3 indicated a marginally significant group $×$ virus $×$ drug interaction ($F_{3,60} = 2.340, p = .082$). Separate analysis of alcohol intake in mice expressing hM4Di in CeA$_{DYN}$ neurons revealed a significant group $×$ drug interaction ($F_{3,38} = 8.521, p < .001$). Following vehicle (saline) administration, mice with a history of CIE alone and CIE+FSS consumed more alcohol than CTL mice that received vehicle ($p < .05$). Furthermore, alcohol intake was significantly greater in the CIE+FSS group than in the CIE-alone condition ($p < .005$), whereas FSS alone did not significantly alter alcohol consumption. Selective silencing of CeA$_{DYN}$ neurons following CNO injection resulted in significant reduction in alcohol intake in the CIE+FSS group ($p < .001$). CNO injection produced a marginal reduction in drinking in the CIE-alone group ($p = .082$) but did not alter alcohol intake in the FSS-alone or CTL groups (Figure 3C). Similar analysis of alcohol consumption in mice treated with control virus indicated a main effect of group ($F_{3,50} = 16.14, p < .001$) but no group $×$ drug interaction ($F_{3,22} = 0.128, p = .831$). As expected, alcohol intake was significantly greater in CIE-alone mice than CTL mice ($p < .05$), and stress further enhanced this elevated drinking (CIE+FSS > CIE-alone) ($p < .01$). Alcohol intake in the FSS-alone group did not differ from the CTL group. CNO injection in mice that harbored the control virus did not alter alcohol drinking in any of the groups (Figure 3D).

To further examine the apparent selective effect of CNO in mice treated with the active (hM4Di-containing) virus, data expressed as a change from the vehicle (saline) condition for each subject were analyzed (Figure 3E). Post hoc analysis of the group $×$ virus interaction ($F_{3,38} = 2.34, p < .05$) indicated that CNO injection significantly reduced alcohol intake (relative to vehicle) only in CIE+FSS mice that harbored active versus control virus ($p < .001$), and this reduction was greater in CIE+FSS mice compared with all other groups that were treated with active virus ($p values < .01$). Thus, inactivation of CeA$_{DYN}$ neurons following CNO injection significantly attenuated the ability of stress (FSS) to further enhance alcohol consumption in CIE-exposed mice, and this effect was only observed in mice treated with the inhibitory (hM4Di) DREADD-containing virus.
Figure 3. Chemogenetic inhibition of CeA<sub>DYN</sub> neurons attenuates stress-enhanced alcohol drinking. (A) For targeted expression of an inhibitory DREADD, Pdyn-ires-Cre mice were bilaterally infused with AAV8-hSyn-DIO-hM4Di-mCherry or AAV8-hSyn-DIO-mCherry into the CeA 2 weeks prior to start of baseline drinking; vehicle or CNO (3 mg/kg) was injected 30 minutes prior to the second and fourth drinking sessions during test 3 in a balanced crossover design (denoted by green arrows). (B) Viral expression was localized to the CeA as indicated by visualization of mCherry fluorescence. (C) Average alcohol intake in mice expressing hM4Di-containing virus (n = 10 or 11/group). In vehicle-treated mice, alcohol consumption was greater in CIE-alone and CIE+FSS groups than in CTL and FSS-alone groups, which did not differ (p < .05). In addition, intake following vehicle injection was greater in CIE+FSS mice than in CIE-alone mice (p < .005). Activation of the inhibitory DREADD expressed in CeA<sub>DYN</sub> neurons via CNO injection resulted in a significant reduction in alcohol intake in the CIE+FSS group compared with those mice receiving vehicle (p < .001). (D) Average alcohol intake in mice treated with control virus (n = 6 or 7/group). Vehicle injection resulted in the expected greater alcohol intake in CIE-alone and CIE+FSS groups compared with the other groups (p < .05), and intake was greater in the CIE+FSS mice than in CIE-alone mice (p < .005). CNO injection did not alter alcohol drinking in any group relative to when those mice received vehicle injection. (E) Change from respective vehicle alcohol intake across treatment and virus groups. CNO injection significantly reduced alcohol intake (relative to vehicle) in CIE+FSS mice that harbored active vs. control virus (p < .001), and this reduction was greater in CIE+FSS mice compared with when CNO was injected in CIE-alone, FSS-alone, and CTL groups that were treated with active virus (p < .01). All values are mean ± SEM. AP, anteroposterior; BLA, basolateral amygdala; CeA, central amygdala; CIE, chronic intermittent ethanol; CNO, clozapine N-oxide; CTL, control; D, dorsal; DREADD; designer receptor exclusively activated by designer drugs; DYN, dynorphin; FSS, forced swim stress; L, lateral; LA, lateral amygdala; M, medial; V, ventral; VEH, vehicle.

<sup>a</sup>Differs from respective baseline levels (p < .05).
Intra-CeA Injection of a KOR Antagonist Blocks Stress Enhancement of Alcohol Drinking in CIE-Exposed Mice

Alcohol intake prior to microinjection of the KOR antagonist during test 3 is shown in Table 2. ANOVA indicated significant main effects of group ($F_{3,64} = 14.823, p < .001$) and test cycle ($F_{2,126} = 75.339, p < .001$) and a group x test cycle interaction ($F_{6,126} = 12.882, p < .001$). Post hoc analyses indicated that alcohol intake in the CIE-alone and CIE+FSS groups during test 1 and test 2 was greater than their respective baseline levels of intake ($p < .05$). In contrast, FSS alone did not alter alcohol drinking in nondependent mice.

Microinjection of norBNI into the CeA during test 3 (Figure 4A, B) selectively attenuated elevated drinking in mice with a history of CIE alone and CIE+FSS without affecting more moderate levels of consumption in FSS-alone and CTL groups (Figure 4C). This finding is supported by analysis of average alcohol intake during the 2 days following vehicle or norBNI microinjection, which revealed a significant group x drug interaction ($F_{3,60} = 6.742, p < .001$). Post hoc analyses showed that vehicle-treated mice with a history of CIE alone and CIE+FSS exposure consumed more alcohol than CTL mice ($p < .005$) and, replicating our earlier finding, alcohol intake was significantly greater in CIE+FSS compared with CIE-alone mice ($p < .05$). Microinjection of norBNI reversed elevated alcohol intake in both CIE-alone and CIE+FSS groups ($p < .01$). Analysis of daily alcohol intake during test 3 revealed a similar profile of results (Figure S2A, B). To evaluate the relative magnitude of the norBNI effect across all groups, data were also analyzed as a difference from the average vehicle intake for each group. ANOVA revealed a significant group x drug interaction ($F_{3,60} = 6.742, p < .001$), and post hoc analysis indicated that while a trend was apparent in the CIE-alone group ($p = .125$), norBNI significantly reduced alcohol intake relative to the respective vehicle condition only in the CIE+FSS group ($p < .001$). Furthermore, the reduction in alcohol drinking following intra-CeA norBNI injection (relative to vehicle) was significantly greater in the CIE+FSS group compared with all other groups, which did not differ from each other ($p < .01$) (Figure 4D). Collectively, these results suggest that blocking KOR signaling in the CeA was especially effective in reducing stress-enhanced drinking in the model. Schematic representation of injection sites for mice that received vehicle or norBNI into the CeA is shown in Figure S3A and B, respectively.

DISCUSSION

Our studies validate the CIE-FSS drinking paradigm as a framework for modeling stress-enhanced alcohol drinking and demonstrate the significant contribution of DYN/KOR activity within the extended amygdala in mediating this behavior. A history of repeated FSS in CIE-exposed mice resulted in escalation of voluntary alcohol consumption, and this was accompanied by elevated Pdyn mRNA expression in the CeA. Targeted chemogenetic silencing of DYN-containing neurons in the CeA completely blocked the ability of stress to enhance alcohol drinking in the model. Furthermore, pharmacological
blockade of KOR within the CeA or BNST normalized drinking in mice with a history of both stress and CIE exposure. Together, these data suggest that CeA^DYN neurons are uniquely responsive to a history of chronic alcohol exposure and stress, and KOR signaling within the CeA and BNST plays an important role in mediating stress-enhanced alcohol drinking.

While chronic alcohol exposure and stress are known to produce dynamic alterations in brain gene expression (51–55), only recently have genomic changes in relation to stress-alcohol interactions been explored (18). This latter study revealed both unique transitory and long-lasting changes in gene expression in the prefrontal cortex associated with stress-enhanced alcohol consumption in the CIE-FSS drinking model. In this study, we show that Pdyn mRNA levels in the CeA are elevated at 30 minutes and 4 hours after FSS exposure only in mice with a history of both FSS and CIE exposure. This change was not observed in other groups (CIE-alone and FSS-alone conditions) that did not exhibit increased alcohol intake relative to the CTL condition. Studies in rats have shown an upregulation in Pdyn mRNA expression in the CeA following chronic alcohol drinking (56) and acute withdrawal from CIE exposure (43). FSS experience also has been reported to increase Pdyn mRNA levels in extended amygdala structures (57,58). Together, these findings indicate that the CeA is highly responsive to stress and chronic alcohol exposure, and changes in Pdyn transcriptional activity may contribute to enhanced motivation to drink following combined stress and chronic alcohol exposure.

The CeA is a key structure within extended amygdala circuitry with rich expression of both DYN and KORS (38–40). In this study, using a validated transgenic mouse model (47) along with a validated DREADD-containing viral construct (35), targeted chemogenetic inactivation of CeA^DYN neurons blocked stress-enhanced alcohol drinking. Vehicle injections in mice expressing the inhibitory (hM4Di) DREADD did not alter alcohol drinking, and reduced alcohol intake in mice injected with CNO is not likely to be attributed to off-target effects of CNO because the ligand did not alter alcohol consumption in mice that received control virus treatment. Using a similar experimental strategy, silencing CeA^DYN neurons was shown to significantly reduce alcohol consumption in a binge-drinking model (35). Likewise, genetic deletion of Pdyn in the CeA reduced alcohol drinking in models of high intake (38). Together, these data indicate that dynorphinergic activity in the CeA plays a significant role in regulating alcohol consumption, including elevated drinking associated with stress.

CeA^DYN neurons produce effects through signaling at KORs locally within the CeA as well as in several projection regions. Studies have shown that the KOR antagonism within the CeA and other extended amygdala structures (e.g., BNST) reduces alcohol drinking (35,42,43,45), and this is congruent with findings showing that systemic administration of KOR antagonists reduces alcohol consumption in a variety of models (20,22,33–36). Results from this study indicate that direct injection of the KOR antagonist norBNI into the CeA or BNST

addressing the problem. We have established a model demonstrating robust and highly reproducible stress-induced elevation of alcohol consumption. Using chemogenetic and pharmacological approaches, we show that DYN/KOR activity within extended amygdala circuitry plays a significant role in mediating the ability of stress to increase drinking in mice with a history of chronic alcohol exposure. These findings align with other preclinical studies showing that long-acting (20,33–35) and short-acting (36,66,67) KOR antagonists reduce high levels of alcohol consumption and relapse-like behavior provoked by stress. Together, these results support clinical studies that target the DYN/KOR system in the development of more effective treatments for individuals presenting with comorbidity of stress-related disorders and AUD.

compared with all other groups, which did not differ from each other (*p < .05). BNST, bed nucleus of the stria; CIE, chronic intermittent ethanol; CTL, control; FSS, forced swim stress; norBNI, nortobinorphimine.

blocked the ability of stress to enhance voluntary alcohol drinking in the CIE+FSS group. Thus, these are the first data to directly implicate a role for DYN/KOR activity within extended amygdala circuitry in contributing to stress-induced excessive drinking. While there is evidence for dynorphinergic projections from the CeA to the BNST (40,50), the extent to which these results are mediated by KOR signaling within the CeA and other projection sites, including the BNST, will require more direct circuitry-based examination.

CeA<sup>DYN</sup> neurons are primarily GABAergic (gamma-aminobutyric acidergic) and known to coexpress other neuropeptides that influence alcohol drinking, such as corticotropin release factor and neurotensin (59,60). Thus, co-release of GABA (gamma-aminobutyric acid) and other peptides may contribute to stress-enhanced drinking in this model, and this possibility cannot be ruled out. However, results from our chemogenetic and pharmacological studies strongly implicate a significant role for engagement of DYN/KOR activity within extended amygdala circuitry in the ability of stress to further elevate alcohol consumption in subjects with a history of chronic alcohol exposure.

While stress-enhanced drinking in the CIE-FSS model has been demonstrated in both female and male mice (61,62), one limitation of this study is that only male mice were used to examine the role of DYN/KOR activity. Sex-related differences in sensitivity to DYN/KOR function have been noted, especially regarding reward and aversion/dysphoria-related behaviors (63–65). Thus, it will be important in future studies to examine whether manipulation of DYN/KOR activity within extended amygdala circuitry produces sex-related differences in stress-enhanced alcohol drinking. This is especially relevant given the high prevalence of co-occurring stress-related disorders and AUD in women (5,8).

In summary, despite stress being a significant contributing factor in heavy drinking, as reflected by high comorbidity of stress-related disorders and AUD, few effective treatments are available, and the lack of preclinical models that reliably demonstrate stress-enhanced drinking has hindered efforts to address the problem. We have established a model demonstrating robust and highly reproducible stress-induced elevation of alcohol consumption. Using chemogenetic and pharmacological approaches, we show that DYN/KOR activity within extended amygdala circuitry plays a significant role in mediating the ability of stress to increase drinking in mice with a history of chronic alcohol exposure. These findings align with other preclinical studies showing that long-acting (20,33–35) and short-acting (36,66,67) KOR antagonists reduce high levels of alcohol consumption and relapse-like behavior provoked by stress. Together, these results support clinical studies that target the DYN/KOR system in the development of more effective treatments for individuals presenting with comorbidity of stress-related disorders and AUD (46,68).
